**ABSTRACT**

Host-associated microbial communities can influence physiological processes of macroorganisms, including contributing to infectious disease resistance. For instance, some bacteria that live on amphibian skin produce antifungal compounds that inhibit two lethal fungal pathogens, *Batrachochytrium dendrobatidis* (Bd) and *B. salamandrivorans* (Bsal). Therefore, differences in microbiome composition among host species or populations within a species can contribute to variation in susceptibility to Bd/Bsal. This study applies 16S rRNA sequencing to characterize the skin bacterial microbiomes of three widespread terrestrial salamander genera native to the western United States. Using a metacommunity structure analysis, we identified dispersal barriers for these influential bacteria between salamander families and localities. We also analyzed the effects of habitat characteristics such as percent natural cover and temperature seasonality on the microbiome. We found that certain environmental variables may influence the skin microbial communities of some salamander genera more strongly than others. Each salamander family had a somewhat distinct community of putative anti-Bd skin bacteria, suggesting that salamanders may select for a functional assembly of cutaneous symbionts that could differ in its ability to protect these amphibians from disease. Our observations raise the need to consider host identity and environmental heterogeneity during the selection of probiotics to treat wildlife diseases.

amphibian, chytridiomycosis, microbiome, metacommunity, salamander, 16S rRNA

## 1 INTRODUCTION

2 A fundamental concept in modern biology is that no organism lives in true isolation.  
3 Organisms are shaped by numerous biotic and abiotic interactions across many different scales  
4 (Bosch and McFall-Ngai 2011; McFall-Ngai et al. 2013). For example, diverse symbiotic  
5 microbes inhabit the bodies of multicellular organisms and play critical roles in metabolism,  
6 immune function, and hormone production (Costello et al. 2012; Muller et al. 2020). Microbial  
7 ecology processes (e.g. dispersal, colonization, and competition) directly influence host-  
8 associated microbial communities (i.e. the microbiome), which in turn impacts host fitness  
9 (Mihaljevic 2012).

10 Most microbiome studies use alpha and beta diversity metrics to understand differences  
11 in microbial composition and diversity among host individuals or taxa (Goodrich et al. 2014).  
12 However, these analyses are often not sufficient to pinpoint biotic and abiotic factors that affect  
13 the assembly of microbiomes (Greenspan et al. 2020). Therefore, interdisciplinary approaches  
14 that combine tools from community ecology and population genetics may provide increased  
15 resolution to explore processes controlling community assembly of host-associated microbiomes,  
16 and the metacommunity framework is one such approach. This framework can be used to  
17 describe patterns and mechanisms behind the distribution of organisms across patches of habitat  
18 (Leibold and Mikkelsen 2002; Leibold and Miller 2004) but is most often used to characterize  
19 the community structure of macro-organisms. More recently, the metacommunity framework has  
20 been applied to understand the role of dispersal, colonization, and competition in shaping  
21 microbial community assembly across local (e.g. hosts) and regional (e.g. populations of hosts)  
22 scales (Mihaljevic 2012; Christian, Whitaker and Clay 2015; Burns et al. 2017). Applying a  
23 hierarchical approach that evaluates symbiont distributions at different ecological scales is  
24 critical to understand the extent to which host or environmental factors shape the assembly of  
25 host-associated microbiomes (Mihaljevic, Hoyer and Johnson 2018).

26 The skin of amphibians is a particularly valuable environment with which to study  
27 bacterial metacommunities due to its importance for host respiration, osmoregulation, and  
28 immune function (Campbell et al. 2012). The bacteria that live on the amphibian skin are on the  
29 front line of defense against diseases such as *Batrachochytrium dendrobatidis* (Bd), a fungal  
30 pathogen that causes chytridiomycosis—one of the deadliest wildlife diseases ever described  
31 (Fisher and Garner 2020). Bd infects the amphibian skin and has a notably broad host range,  
32 making it a suspect in the declines of over 500 species from around the world (Scheele et al.  
33 2019, 2020; Lambert et al. 2020). Bd's sister species, *B. salamandrivorans* (Bsal), is an  
34 emerging pathogen that was found to be associated with die-offs of European salamander  
35 populations after likely being introduced from Asia through the pet trade (Martel et al. 2013,  
36 2014; Fitzpatrick et al. 2018). The high levels of susceptibility observed in European  
37 salamanders suggest that Bsal is highly virulent when introduced to naïve populations (Yap et al.  
38 2015; Berger et al. 2016). The emergence of Bsal in Europe has raised concerns about its  
39 potential threat to salamander biodiversity on other continents.

40 The structure and function of the amphibian skin microbiome has been shown to play an  
41 important role in Bd and Bsal disease dynamics (Rebollar and Harris 2019). Certain cutaneous  
42 bacteria found on amphibians are known to produce compounds that inhibit *Batrachochytrium*  
43 in-vitro (henceforth referred to as anti-Bd bacteria; Becker et al. 2009; Woodhams et al. 2015).  
44 Some bacteria have been shown to modulate host immune responses to chytridiomycosis  
45 (Woodhams et al. 2020) and have even been used successfully as probiotic treatments for  
46 threatened amphibian species (Harris et al. 2009; Muletz et al. 2012; Bletz et al. 2013;

1  
2  
3 1 Kueneman et al. 2016). The overall community composition of the skin microbiome prior to Bd  
4 2 infection relates to disease dynamics in many cases, suggesting that species interactions are  
5 3 playing an important role in disease defense (Walke et al. 2015; Bates et al. 2018; Becker et al.  
6 4 2019). Because numerous factors can contribute to variation in amphibian skin microbiomes  
7 5 (Kueneman et al. 2014; Jiménez and Sommer 2017), it is essential to holistically evaluate the  
8 6 distribution of key symbionts and the biotic and abiotic factors that influence their distributions  
9 7 (Loudon et al. 2016).

10 8  
11 9 Given the potential for continued spread of Bsal, evaluating patterns of skin microbial  
12 10 symbiont distribution is an important task for vulnerable salamanders outside of the current Bsal  
13 11 range. Californian salamander populations are predicted to be particularly vulnerable to Bsal  
14 12 invasion based on habitat suitability models for the fungus and patterns of legal and illegal  
15 13 salamander trade into the U.S. (Yap et al. 2015; Richgels et al. 2016). This looming threat  
16 14 emphasizes the need to study the microbial ecology of some of California's native salamanders'  
17 15 skin microbiomes (Abarca et al. 2018). We compared the skin microbiota of five different  
18 16 salamander species that are native to the San Francisco Bay Area. Based on laboratory studies,  
19 17 we know that three of these species (*Ensatina eschscholtzii*, *Taricha granulosa*, and *T. torosa*)  
20 18 are vulnerable to Bsal (Martel et al. 2014; Piovia-Scott et al. 2019), while two of these species  
21 19 (*Batrachoseps attenuatus* and *T. rivularis*) have not been tested, though *T. rivularis* is likely  
22 20 susceptible due to its relatedness to the other *Taricha* in this study. We compared patterns of  
23 21 bacterial taxa distribution for the overall skin microbiome as well as for a subset of microbial  
24 22 taxa that have been characterized as anti-Bd across eight localities using 16S rRNA sequencing.  
25 23 In addition to traditional microbiome community analyses, we also characterized various metrics  
26 24 of metacommunity structure in order to evaluate the pattern of symbiont bacteria distribution  
27 25 across all salamanders. We then evaluated how the distribution of these bacteria is influenced by  
28 26 host and environmental factors. Applying these same approaches to potential anti-Bd bacteria  
29 27 allowed us to also evaluate how these potentially important symbionts are influenced by host and  
30 28 environmental factors.

## 31 29 **MATERIALS & METHODS**

### 32 30 **Field Methods**

33 31 We sampled terrestrial salamanders (*Taricha granulosa*, *T. torosa*, *T. rivularis*,  
34 32 *Batrachoseps attenuatus*, and *Ensatina eschscholtzii* ssp. *xanthoptica* and *oregonensis*) during  
35 33 the fall and winter (rainy season) between October 2018 and December 2018 at the University of  
36 34 California (UC), county, and federal properties throughout the San Francisco Bay Area (Figure  
37 35 1). We restricted our sampling to terrestrial individuals only to minimize microbiome variation in  
38 36 response to habitat variation. Salamander sampling localities consisted of creek riparian zones  
39 37 composed of a mix of California oak (*Quercus* sp.), California bay (*Umbellularia* sp.) and/or  
40 38 redwoods (*Sequoia sempervirens*). We located salamanders through visual detection and log  
41 39 flipping. Immediately after capture, we placed animals in clean plastic bags and marked each  
42 40 animal's capture location. New gloves were donned before handling each animal to prevent  
43 41 cross-contamination of microbiome samples. At each locality, we sampled up to 21 salamanders  
44 42 of each genus (Figure 1; Table S1).

45 43 Before swabbing, we rinsed each animal with approximately 250 mL of sterile distilled  
46 44 water to remove transient microbes (Culp, Falkinham and Belden 2007). We then used a sterile  
47 45 cotton-tipped applicator to swab the dorsal skin surface 30 times, then stored the swab in a sterile  
48 46 1.5-mL microcentrifuge tube. We used a second swab to swab the dorsal and ventral surface 15

1  
2  
3 1 times each and used this swab for another study. Given the ventral, feet, and dorsal communities  
4 2 do not differ in other salamanders and anurans (Hernandez-Gomez et al., 2017; Sabino-Pinto et  
5 3 al., 2016), we used only the dorsal skin surface swabs for the current study. We measured each  
6 4 animal's tail and snout-vent length to the nearest millimeter using calipers and weighed them to  
7 5 the nearest tenth of a gram on a 500 g digital scale. We returned animals to their exact flagged  
8 6 location immediately after processing. We stored the skin swab samples on dry ice until they  
9 7 were transported to the laboratory and stored in a -80°C freezer. We handled all animals using  
10 8 the approved University of California - Berkeley IACUC protocol (AUP-2015-01-7083).  
11  
12  
13 9

## 10 **Environmental Data Collection**

11 For each sampling locality, we recorded GPS coordinates at the position where sampling  
12 12 began. Given that we collected salamanders along streams, we used the USGS National  
13 13 Watershed Boundary Dataset to identify the HUC 12-level boundaries overlapping with our  
14 14 sampling locations in QGIS (version 3.2.1). We applied these boundaries to characterize the  
15 15 percentage of land with natural cover using the CALVEG GIS dataset (USDA Forest Service,  
16 16 Remote Sensing Laboratory) and to extract bioclimatic variables from the WorldClim dataset.  
17 17 We used a principal component analysis to transform the bioclimatic variables (highly  
18 18 correlated) into a new set of uncorrelated variables. The sample scores of the first two principal  
19 19 components were retained for subsequent analyses as together these explained 99.85% of the  
20 20 bioclimatic variation captured across our sites. These two principal components exhibited strong  
21 21 correlations with temperature seasonality ( $r = 0.800$ ; PC1 explained variance = 95.38%) and  
22 22 annual precipitation ( $r = -0.996$ ; PC2 explained variance = 4.47%). We will refer to these two  
23 23 principal components as temperature seasonality (PC1) and annual precipitation (PC2) hereafter.  
24  
25

## 25 **Laboratory Methods**

26 We processed skin samples using the protocol outlined in Hernández-Gómez et al.  
27 (2017). To isolate microbial DNA from skin swabs, we used the DNeasy PowerSoil Kit (Qiagen  
28 N.V., Hilden, Germany). To control for contamination, we included negative extraction controls  
29 (i.e. unused swabs) and researcher glove swabs. We amplified the bacterial 16S rRNA gene V4  
30 region using primer pair F515/R806 attached to barcode/sequencer adaptor connector sequences.  
31 We ran each sample in triplicate, with each 15- $\mu$ L reaction containing 5  $\mu$ L of template DNA,  
32 7.5  $\mu$ L of 2X MyTaq Master Mix (Bioline, Tauton, MA, USA), 1.0  $\mu$ L of 1 nM forward and  
33 reverse primers, and 1.5  $\mu$ L of sterile water. PCR conditions consisted of 94°C for 3 min, 30  
34 cycles of 94°C for 45s, 50°C for 60s, and 72°C for 90s, followed by 72°C for 10 minutes. We  
35 pooled triplicate PCR products and cleaned them using the Qiagen UltraClean PCR Clean-up kit.

36 We performed a second PCR on microbiota amplicons to ligate dual-index barcodes  
37 paired with Illumina sequencing adaptors to the ends of amplicons. The 15  $\mu$ L PCR reactions  
38 consisted of 5.0  $\mu$ L clean amplicons, 7.5  $\mu$ L 2X MyTaq MasterMix, 1.0  $\mu$ L of 1 nM forward and  
39 reverse barcode primers (Hernández-Gómez et al. 2017), and 1.5  $\mu$ L of sterile water. We  
40 quantified the PCR products using a Qubit Fluorometer (Invitrogen Corp, Carlsbad, CA, USA),  
41 pooled samples in equimolar amounts, and cleaned the sample pool using the UltraClean PCR  
42 Clean-Up kit. The sample pool was submitted to the California institute for Quantitative  
43 Biosciences Vincent J. Coates Genomics Sequencing Laboratory and sequenced on a MiSeq  
44 platform (Illumina Inc., San Diego, CA, U.S.A.) using the Reagent Kit V3 to produce 300 bp  
45 paired-end reads.  
46

## 1 Data Filtering and Analysis

2 We filtered raw reads using Trimmomatic (Bolger, Lohse and Usadel 2014) to remove  
3 adaptor sequences, bases below the threshold quality of phred-20 from both ends of the reads,  
4 and any resulting reads under 30 bp in length. We then paired the quality-trimmed forward and  
5 reverse reads using PANDAseq (Masella *et al.* 2012). We only used reads that paired  
6 successfully in the subsequent analyses.

7 We implemented established sequence read processing pipelines to filter erroneous reads,  
8 generate amplicon sequence variants (ASVs - sequencer error-corrected unique DNA  
9 sequences), and to create a representative sequence phylogeny and assign taxonomy to ASVs.  
10 We processed reads using the Quantitative Insights Into Microbial Ecology version 2.2018.4  
11 (QIIME2) pipeline (Bolyen *et al.* 2019). We used the DADA2 plugin to quality filter,  
12 dereplicate, remove chimeras and denoise reads using default settings (clustering at 99%  
13 similarity; Callahan *et al.* 2016). We generated a phylogeny using MAFFT aligned representative  
14 ASV sequences in FastTree2 (DeSantis *et al.* 2006; Price, Dehal and Arkin 2010). We ran the  
15 ASV table through the package *decontam* in R to identify ASVs associated with glove  
16 samples/negative extraction controls and removed identified contaminants from the salamander  
17 skin swab ASV table (Davis *et al.* 2018). We also filtered out ASVs whose taxonomy matched  
18 chloroplast or mitochondria as these were not the target of our sequencing library preparation  
19 protocol. To standardize sequencing depth throughout all samples, we rarefied the filtered ASV  
20 table to 5038 sequences per sample. All control samples were rarefied out of our analysis.

21 We transferred the rarefied ASV table and Newick phylogeny to R (version 3.5.1) for  
22 further analyses. We calculated three distinct alpha diversity metrics using the R packages *vegan*  
23 (Oksanen *et al.* 2020) and *picante* (Kembel *et al.* 2010): community richness (i.e. number of  
24 observed ASVs per sample), evenness (i.e. Shannon Diversity Index) and phylogenetic diversity  
25 (i.e. Faith's phylogenetic diversity). To evaluate differences in community composition across  
26 samples, we used the R packages *GUniFrac* (Chen 2015) and *vegan* to calculate two separate  
27 beta diversity metrics: unweighted UniFrac distances and Bray-Curtis dissimilarities. We chose  
28 to include these beta diversity metrics as they account for differences in presence/absence of  
29 bacterial lineages among samples (unweighted UniFrac) and non-phylogenetic abundance-based  
30 differences among samples (Bray-Curtis). In addition, we characterized the core microbiota  
31 (ASVs present in at least 70% of individuals) for each species.

32 We queried each ASV representative sequence using BLAST against a database of 16S  
33 rRNA sequences from anti-Bd bacteria (Woodhams *et al.* 2015). ASVs with 100% similarity to  
34 the query were used to generate an anti-Bd ASV table. Using the new ASV table, we calculated  
35 the anti-Bd community richness (i.e. the number of inhibitory ASVs) and the proportion of anti-  
36 Bd reads for each sample.

## 37 Statistical Analysis

38 We performed all statistical analyses using a hierarchical design with the goal of  
39 evaluating effects of host and environmental factors on the skin microbiome of salamanders.  
40 First, we evaluated how host species and environment shaped skin microbial communities and  
41 possibly anti-Bd bacteria among all salamanders sampled. Given that genus identity was  
42 predicted to be a strong influencer, we also assessed how the skin microbiota of each genus was  
43 influenced by host and environment factors independently. Because *T. torosa* and *T. granulosa*  
44 can be difficult to differentiate morphologically and their ranges overlap in the San Francisco  
45 Bay Area, we grouped all *Taricha* individuals by genus and used genus assignment for all  
46

1 statistical comparisons. To account for multiple comparisons, all  $p$ -values were Bonferroni-  
2 corrected.

#### 3 4 *Effects of host and environment on alpha diversity, beta diversity and ASV distribution*

5 We calculated body condition indices for each salamander by obtaining the least squares  
6 regression residuals of log-transformed mass and total body length. This metric has shown to  
7 accurately represent estimates of body reserves in amphibians and other vertebrates (Ardia 2005;  
8 Schulte-Hostedde *et al.* 2005).

9 To evaluate how host and environmental variables influenced the diversity, structure, and  
10 distribution of ASVs across all salamanders, we used linear mixed models to assess which  
11 variables influence alpha diversity metrics in terrestrial salamanders. Either community richness,  
12 evenness, or phylogenetic diversity were entered as dependent variables; genus, percent natural  
13 cover, temperature seasonality (PC1), and annual precipitation (PC2) as fixed independent  
14 variables (we did not include body condition indices in these analyses given the large variation in  
15 morphology across the three genera studied); and locality as a random independent variable. We  
16 implemented AICc ranking to exclude non-significant fixed variables using the R package  
17 *MuMIn* (Barton 2020). We evaluated differences in alpha diversity within each genus in a similar  
18 fashion, replacing the genus fixed variable with body condition indices. We used PERMANOVA  
19 tests (R package *vegan*) to evaluate how host and environmental variables contribute to  
20 community composition overall and at the genus level.

21 To evaluate differences in composition across all salamanders, we inputted unweighted  
22 UniFrac and Bray-Curtis dissimilarities as dependent variables; genus, percent natural cover,  
23 temperature seasonality-PC1, and annual precipitation-PC2 as fixed variables; and locality  
24 identity as a random factor (i.e. permutations were performed within localities). As in the alpha  
25 diversity analysis, we ran genus-specific PERMANOVAS using the same variables, except with  
26 body condition indices as a fixed variable instead of genus identity. To visualize community  
27 structure, we generated NMDS plots using unweighted UniFrac and Bray-Curtis dissimilarities.  
28 Also, to assess for the effect of geographic distance on community composition we ran Mantel  
29 tests between site pairwise Euclidean distances and unweighted UniFrac/Bray-Curtis  
30 dissimilarities. We repeated the Mantel test using these same distances within each genus.

31 We analyzed the metacommunity structure of salamander skin communities using the  
32 package *metacom* in R (Dallas 2014). We restricted this analysis to ASVs present in greater than  
33 10% of all individuals as recommended by Dallas (2014) to eliminate rare ASVs which may  
34 complicate sample/ASV ordination. We ranked ASVs according to their distribution and  
35 salamander skin samples according to their composition using reciprocal averaging (i.e.  
36 correspondence analysis). Then, we calculated the three elements of metacommunity structure  
37 (EMS): coherence, turnover, and boundary clumping (Leibold and Mikkelsen 2002; Presley,  
38 Higgins and Willig 2010). EMS values are calculated for each dataset, then a permutation test is  
39 used to assess the significance of the observed EMS indices. Because we were working with a  
40 very large dataset, we restricted permutations to 99 and allowed null matrices to have empty  
41 rows and columns as recommended by Dallas (2014) to ease computation time. These three  
42 statistical tests are used in a dichotomous key-manner to classify the ranked matrix's  
43 metacommunity structure against those of idealized metacommunity structures (Table S3)  
44 described in Presley *et al.* (2010).

45 Coherence evaluates the number of absences ASVs have within their distribution across  
46 the ranked samples and is used to infer the degree that species co-occur (Leibold and Mikkelsen

2002). Metacommunities with negative coherence resemble a ‘checkerboard’ pattern because of mutual exclusion between ASVs, those with a coherence value of zero display a ‘random’ pattern of absences within ranges, and those with positive coherence display a consistent presence of ASVs within their range. Turnover assesses the rate of ASV replacements that occurs between samples and is used to assess changes in community composition. A metacommunity that displays negative turnover exhibits a loss of ASVs without replacement across the sample gradient resulting in a ‘nested’ structure and a metacommunity that possesses positive turnover exhibits a change in ASV composition along the sample gradient. Boundary clumping is used to differentiate the patterns of species turnover in metacommunities with positive coherence and positive turnover. The test uses Morisita’s overlap index to evaluate whether groups of ASVs share boundaries (Morisita’s Index > 0) resulting in discrete communities across the sample gradient, whether ASV boundaries are evenly distributed across the range (Morisita’s Index < 0) resulting in gradual composition change along the sample gradient, or whether there is a random pattern in the distribution of ASV boundaries across the range (Morisita’s Index = 0). We implemented the default ‘r1’ to characterize the significance of the EMS and compared them against those of idealized metacommunity structures (Table S3) described in Presley et al. (2010).

To evaluate the effect of host and environmental variables in structuring salamander community ordination, we performed Pearson correlation tests between sample ordination scores and percent natural cover, temperature seasonality-PC1, and annual precipitation-PC2. We ran a Kruskal-Wallis test to evaluate if genus (i.e. a categorical variable) influences sample ordination scores. An identical analysis was performed within each genus; however, we tested for correlations between body condition indices or environmental variables and salamander ordination using Pearson correlations tests.

### *Effects of host and environment on richness, relative abundance and turnover of possible anti-Bd bacteria*

We evaluated how host and environmental variables influence the richness, relative abundance (proportion of reads per sample identified as inhibitory) and distribution of anti-Bd ASVs across all salamanders and within each genus. We used linear mixed models to independently assess which variables influence anti-Bd ASV richness and relative abundance. We tested genus, percent natural cover, temperature seasonality (PC1), and annual precipitation (PC2) as fixed independent variables and locality as a random independent variable. As done before, we repeated this analysis for each genus and added body condition indices as fixed variables. We also used ranked AICc scores to exclude non-significant variables.

We analyzed the metacommunity structure of anti-Bd bacteria across all salamanders and within each genus using the package *metacom* in R as described above. To evaluate effects of host and environmental variables in structuring anti-Bd bacteria distribution across salamanders, we performed Pearson correlation tests between sample ordination scores and percent natural cover, PC1, and PC2. We ran a Kruskal-Wallis H test to evaluate if genus (i.e. a categorical variable) correlates with ordination scores. For the intra-genus comparisons, we evaluated Pearson correlations between sample ordination scores, body condition indices, and the environmental variables.

## **RESULTS**

1  
2  
3  
4 1 After quality control and filtering, we used reads from 192 skin samples ( $n = 92$   
5 2 *Batrachoseps attenuatus*,  $n = 57$  *Ensatina eschscholtzii*, and  $n = 43$  *Taricha* sp). The total  
6 3 number of reads was 4,337,652, with 55,333 unique ASVs (Amplicon Sequence Variants) across  
7 4 all skin samples. We detected between 47 and 770 bacterial ASVs on each salamander. We  
8 5 identified ASVs assigned to *Pseudomonas viridiflava*, *Variovorax paradoxus*, and *Rhizobium* sp.  
9 6 across all genera of salamanders sampled. The *Taricha* core microbiome was dominated by  
10 7 ASVs assigned to an *Arthrobacter* sp. and *Pseudomonas viridiflava*. The core microbiomes of  
11 8 *Ensatina* and *Batrachoseps* were dominated by *P. viridiflava* and an ASV in the family  
12 9 Aeromonadaceae (Fig. 2). All of these bacteria are classified as anti-Bd besides the ASV in the  
13 10 family Comamonadaceae.  
14 11

### 12 12 **Effects of host and environment on alpha diversity, beta diversity and ASV distribution**

13 13 Genus significantly predicted skin richness, Shannon Diversity indices, and Faith's  
14 14 phylogenetic diversity indices at a global scale (Table 1). Across all salamanders, our model  
15 15 selection pipeline resulted in models that did not indicate any environmental effects on alpha  
16 16 diversity across the landscape. Post-hoc analyses showed higher alpha diversities in *Ensatina*  
17 17 salamanders compared to *Batrachoseps* and *Taricha* (Fig. 3). Within *Ensatina*, all variables were  
18 18 dropped for richness and Shannon diversity indices and annual precipitation (PC2) had a  
19 19 negative effect on Faith's phylogenetic diversity indices. Within *Batrachoseps* and *Taricha*, all  
20 20 environmental variables were removed during variable selection or had no significant  
21 21 associations with alpha diversities.  
22 22

23 23 Genus also explained the largest portion of the variation observed in Bray-Curtis  
24 24 dissimilarities across all salamanders followed by temperature seasonality (PC1; Table 2). We  
25 25 detected a marginal effect from environmental variables on unweighted UniFrac dissimilarities,  
26 26 signifying that the effects of environmental variables on community composition were specific to  
27 27 the turnover of rare bacteria. Within *Batrachoseps*, *Ensatina* or *Taricha*, none of the  
28 28 environmental or host-specific variables significantly explained the grouping of samples. When  
29 29 visualizing all salamanders together, we observed loose clustering by genus identity in the  
30 30 NMDS plots generated from unweighted UniFracs and Bray-Curtis dissimilarities (Figure 4); but  
31 31 *Taricha* salamanders were amongst the most conserved of the three (Figure 4B). Still, Genus-  
32 32 specific NMDS plots displayed a pattern of clustering by location among the first or second axis  
33 33 across all beta diversity metrics used (Figure 5). In addition, Euclidean geographical distances  
34 34 correlated with skin microbiota Bray-Curtis distances in our global comparison (including all  
35 35 salamander genera:  $r = 0.086$ ,  $p = 0.008$ ) and within the two plethodontid salamanders only  
36 36 (*Batrachoseps*:  $r = 0.114$ ,  $p = 0.012$ ; *Ensatina*:  $r = 0.238$ ,  $p = 0.012$ ). We did not detect  
37 37 correlations between geographic Euclidean geographical distances and unweighted UniFrac  
38 38 distances.  
39 39

40 40 Across all salamanders, skin microbial communities displayed a Clementsian structure  
41 41 (positive, significant coherence, positive, significant turnover, positive ( $>1$ ), significant boundary  
42 42 clumping; Table 3). In addition, percent natural cover ( $r = 0.49$ ,  $p < 0.001$ ), temperature  
43 43 seasonality (PC1;  $r = 0.68$ ,  $p < 0.001$ ), annual precipitation (PC2;  $r = -0.37$ ,  $p < 0.001$ ) and genus  
44 44 identity  $X^2 = 98.74$ ,  $df = 2$ ,  $p < 0.001$ ) all correlated with the ordination scores of salamanders.  
45 45 However, salamanders were ordered into family clusters by the reciprocal averaging protocol  
46 46 (Figure S1), suggesting a strong effect of host phylogeny on the distribution of bacteria. The  
47 47 metacommunity structures within each salamander genus displayed positive coherence, negative  
48 48 turnover, and positive boundary clumping, aligning with the idealized nested Clementsian  
49 49  
50 50  
51 51  
52 52  
53 53  
54 54  
55 55  
56 56  
57 57  
58 58  
59 59  
60 60

1 structure (Table 3; Figure S1). *Batrachoseps* salamanders experienced correlations between  
2 sample ordination scores and annual precipitation (PC2;  $r = -0.40$ ,  $p < 0.001$ ) and body condition  
3 indices ( $r = -0.25$ ,  $p = 0.0175$ ). Percent forest cover ( $r = 0.53$ ,  $p < 0.001$ ) was significantly  
4 associated with the ordination of *Ensatina* salamanders, and *Taricha* ordinations correlated with  
5 annual precipitation (PC2;  $r = 0.50$ ,  $p = 0.003$ ; Figure S1). Together, these patterns suggest that  
6 skin microbial communities among salamander genus are discrete; however, within each genus  
7 there is a clumped loss of ASVs among groups of salamanders that depends on environmental  
8 factors.

### 9 10 **Effects of host and environment on anti-Bd bacterial richness, relative abundance and** 11 **metacommunity structure**

12 None of the tested fixed variables were associated with the richness of anti-Bd bacteria  
13 across all salamanders. Within each salamander, we only observed a significant negative effect  
14 of percent natural cover on the richness of *Ensatina* anti-Bd bacteria ( $F_{1,6} = 13.05$ ,  $p = 0.0448$ ).  
15 Among the three salamander genera, *Ensatina* (mean  $\pm$  SE;  $12.49 \pm 0.71$ ) possessed a greater  
16 number of predicted anti-Bd bacteria on skin microbiomes compared to *Batrachoseps* ( $11.21 \pm$   
17  $0.48$ ) and *Taricha* ( $11.32 \pm 0.48$ ). Genus was the only variable significantly associated with anti-  
18 Bd bacteria relative abundance across all salamanders ( $F_{2, 178} = 6.08$ ,  $p = 0.0112$ ). The  
19 microbiome of *Taricha* possessed the highest total relative abundance of anti-Bd bacteria ( $0.14 \pm$   
20  $0.016$ ), followed by *Ensatina* ( $0.11 \pm 0.011$ ) and *Batrachoseps* ( $0.085 \pm 0.008$ ). Considering each  
21 salamander genus separately, we did not find associations between host or environmental factors  
22 and the relative abundance of anti-Bd bacteria.

23 Anti-Bd bacteria metacommunity structure was also characterized as Clementsian  
24 (positive, significant coherence, positive, significant turnover, and positive ( $>1$ ), significant  
25 boundary clumping; Table 3). Percent natural cover ( $r = 0.29$ ,  $p < 0.001$ ) and genus identity ( $X^2$   
26  $= 19.40$ ,  $df = 2$ ,  $p < 0.001$ ) both correlated with sample ordination scores. These patterns are  
27 confirmed by our visualization of metacommunity structure (Figure 6), where a salamander  
28 family gradient can be observed along the salamander community axis. Within each genus  
29 (Table S4) we detected either a Clementsian structure (*Batrachoseps*) or quasi-Clementsian  
30 structures (*Ensatina* and *Taricha*). Quasi-Clementsian structure is associated with positive  
31 boundary coherence, positive turnover (n.s.) and positive boundary clumping. Quasi-  
32 Clementsian structures are similar to the idealized Clementsian structure, except the range of  
33 turnover is indistinguishable from random. Among *Batrachoseps*, salamander ordination scores  
34 did not correlate with environmental factors or body condition. The ordination scores of *Ensatina*  
35 correlated with percent forest cover ( $r = -0.35$ ,  $p = 0.029$ ) only, while none of the individual and  
36 environmental variables correlated with the ordination of *Taricha* samples.

### 37 38 **DISCUSSION**

39 Incorporating community ecology into microbiological studies is useful for identifying  
40 factors that shape the distribution of key microbes in different habitats. Applying this approach  
41 to host-associated microbiomes presents us with an opportunity to simultaneously explore host  
42 and environmental factors that may influence key symbionts. In this study, we assessed the  
43 composition and distribution of bacteria that live on the skin of three genera of salamanders from  
44 nine sampling localities in California. We found that the core microbiomes of *Taricha*, *Ensatina*,  
45 and *Batrachoseps* are almost exclusively composed of bacterial amplicon sequence variants  
46 (ASVs) that match with strains that inhibit *Bd in vitro*. Of the three salamander genera, *Ensatina*

1  
2  
3 1 microbiomes had a higher skin bacterial alpha diversity than *Batrachoseps* and *Taricha* and  
4 2 bacterial community composition of the skin microbiotas clustered primarily by genus. Finally,  
5 3 metacommunity structure analysis allowed us to identify host identity as a major boundary in the  
6 4 distribution of bacterial ASVs across our salamander samples. When each species'  
7 5 metacommunity was considered separately, the ordination scores of the salamanders correlated  
8 6 with one or more environmental variables.  
9 7

### 11 8 **Host identity is a strong predictor of microbiome structure and symbiont distribution in** 12 9 **terrestrial salamanders**

13 10 Previous studies have assigned either host taxonomy (Jani and Briggs 2014; Kueneman et  
14 11 al. 2014; Walke et al. 2014; Belden et al. 2015; Sabino-Pinto et al. 2016; Prado-Irwin et al. 2017;  
15 12 Abarca et al. 2018) or environmental variation (Bird et al. 2018; Muletz Wolz et al. 2018; Varela  
16 13 et al. 2018; Ellison et al. 2019; Kueneman et al. 2019) as the predominant factor associated with  
17 14 amphibian microbiome variation. In our study, genus identity strongly correlated with the  
18 15 structuring of skin microbial communities and the distribution of ASVs among *Batrachoseps*,  
19 16 *Ensatina* and *Taricha* followed by climatic variables and land cover. We also noted differences  
20 17 in ASV distribution patterns between the salamander genera. For example, plethodontid  
21 18 salamanders experienced a decay in skin microbiome similarity with distance, whereas this  
22 19 pattern was not evident in *Taricha*. Temperature seasonality and annual precipitation different  
23 20 among our sites, and within each genus, we found correlations between climatic variables,  
24 21 natural cover and ASV distribution.  
25 22

26 23 There are numerous ecological and physiological characteristics that could contribute to  
27 24 skin microbiome assembly differences among communities of sympatric salamanders. The three  
28 25 genera we included represent two families of salamanders (Plethodontidae and Salamandridae)  
29 26 that have diverged for at least 150 million years (Zhang and Wake 2009). These salamander  
30 27 families tend to use similar microhabitats for at least part of the year and are therefore exposed to  
31 28 a similar microbial pool. Thus, variation in skin physiology, immune function, behavior, and/or  
32 29 reproductive modes between these taxa could result in different selection pressures among  
33 30 individuals (Stebbins and McGinnis 2018 AmphibiaWeb 2020). Of particular interest is the  
34 31 highly conserved microbiome observed in *Taricha*, and what the high prevalence of bacteria  
35 32 such as *Pseudomonas viridiflava* mean for individual fitness. Similarities in microbiota  
36 33 composition throughout the range may be related to *Taricha*'s life history, as all species of  
37 34 Pacific newts are highly vagile aquatic-breeders that migrate between land and aquatic  
38 35 environments to mate (AmphibiaWeb 2020). It is also possible that *Taricha* retain associations  
39 36 with critical symbiotic bacteria that contribute to other crucial physiological functions (e.g.  
40 37 toxicity). Tetrodotoxin (TTX), a powerful neurotoxin found on the skin of *Taricha*, has been  
41 38 quantified in bacterial cultures derived from their skin (Vaelli et al. 2020). If TTX is generated  
42 39 solely by symbiotic bacteria, co-dependence between *Taricha* and one or more TTX-producers  
43 40 could result in commonalities in core bacteria across the range of the species, as has been  
44 41 observed in other systems, where symbiotic bacteria that facilitate physiological functions  
45 42 comprise a significant part of their core microbiome (Ainsworth et al. 2015). While microbial  
46 43 community functionality is out of the scope of our study, our results suggest the need for future  
47 44 investigations into the importance of conserved microbiomes on pathogen and predator defenses  
48 45 in amphibians.  
49 46

### 50 46 **Distribution of anti-Bd bacteria across sympatric salamanders is tied to host identity**

1  
2  
3  
4 1 The few microbiome papers that have incorporated metacommunity theory when  
5 2 evaluating patterns of microbial community composition have mostly been performed outside of  
6 3 the amphibian realm (Van Der Gucht et al. 2007; Costello et al. 2012; Burns et al. 2017; Toju,  
7 4 Tanabe and Sato 2018; Cleary et al. 2019; Brown et al. 2020, but see Hernández-Gómez et al.  
8 5 2017). The present study provides additional insight into the use of this analysis to track the  
9 6 distribution of important symbionts across three sympatric genera of terrestrial salamanders.  
10 7 Although many ASVs were found in all three genera, skin microbial metacommunities exhibited  
11 8 a high degree of turnover along the sample gradient for both overall and anti-Bd bacteria,  
12 9 meaning that individuals at both extremes of the ordination possessed very different community  
13 10 assemblies (Figures 6 and S1). In our dataset, this compartmentalization correlated strongly with  
14 11 the two families of salamanders. Because our salamander families were sympatric, and often  
15 12 found using the same microhabitats (e.g. under the same log), our results show heterogeneity in  
16 13 the association between salamander families and anti-Bd bacteria. Given the contribution of anti-  
17 14 Bd bacteria to disease resistance, divergent anti-Bd bacteria between salamander families could  
18 15 translate into different mechanisms and magnitudes of pathogen protection (Becker et al. 2015),  
19 16 or differences in the maintenance of microbial symbionts through the production of antimicrobial  
20 17 peptides (AMPs; Kung et al. 2014; Flechas et al. 2019). While our methodology cannot  
21 18 distinguish between these two probable mechanisms, our study highlights the need to continue to  
22 19 evaluate co-evolutionary associations between hosts and relevant members of their natural  
23 20 microbiotas.  
24  
25  
26  
27

### 22 **Relative abundance, richness and distribution of putatively anti-Bd bacteria within** 23 **salamander species are linked to environmental factors**

24 Our metacommunity structure analysis allowed us to evaluate host and environmental  
25 25 factors that may shape the distributions of anti-Bd bacteria within each genus. Since the  
26 26 microbiome composition on the skin of these animals may protect them against  
27 27 *Batrachochytrium*-induced chytridiomycosis (Loudon et al. 2014; Becker et al. 2015), nested and  
28 28 quasi-Clementsian assemblies of bacteria within each genus could indicate the presence of  
29 29 multiple types of “functional assemblies” of bacterial taxa. None of the environmental variables  
30 30 we used correlated with the ordination of *Ensatina* salamanders. However, percent natural cover  
31 31 had a significant effect on the distribution of bacteria among *Taricha*, and *Batrachoseps* was  
32 32 significantly affected by temperature seasonality. These observations imply that different anti-Bd  
33 33 bacteria could provide protection across a species range, and that the assembly of these  
34 34 communities is sensitive to habitat characteristics. It is important to note that temperature  
35 35 seasonality and annual precipitation can also have an impact on the prevalence of Bd in the  
36 36 landscape and this could also influence pathogen burden on the populations (Longo and Zamudio  
37 37 2017). Moving forward, characterizing how various anti-Bd bacterial assemblies contribute to  
38 38 host immunity and pathogen growth is crucial for understanding the dynamics associated with  
39 39 microbiome-derived pathogen resistance across the landscape.  
40  
41  
42

### 41 **Conclusion**

42 In the event of future amphibian chytrid fungus outbreaks in California, our study can  
43 43 serve as a valuable reference of the distribution of functionally important bacteria among these  
44 44 native salamanders (West et al. 2019). Quantifying the distribution of putative anti-Bd bacteria  
45 45 on the skin across different populations allows us to infer whether there are natural defenses  
46 46 already present on their skin that may give these salamanders a chance against the potential  
47  
48

1  
2  
3 1 threat of Bsal and whether any of these naturally associated bacterial taxa could be augmented  
4 2 using cutaneous probiotics, which have been successfully used to protect other amphibian  
5 3 species from chytridiomycosis (Harris et al. 2009; Muletz et al. 2012; Kueneman et al. 2016;  
6 4 Woodhams et al. 2016). The application of metacommunity structure analysis allowed us to  
7 5 compare the effects of host-specific and habitat-specific characteristics on ASV and anti-Bd  
8 6 bacteria distribution. More importantly, we were able to quantify and visualize the  
9 7 compartmentalization between sympatric terrestrial salamanders across a certain degree of  
10 8 habitat heterogeneity. Our results demonstrate that the appropriate selection and application of  
11 9 probiotics may depend on specific factors such as genus and even specific locality. This will be  
12 10 important if the goal is to bolster the functional assemblies that are already present on the skin of  
13 11 these ecologically important amphibians (Bletz et al. 2013; Woodhams et al. 2016).

14 12 Our observations come with the caveat that we used 16S rRNA sequences to infer  
15 13 specific functions that are not related to our genetic marker; thus, future work in this system  
16 14 should consider measuring whether predictions of anti-Bd functionality using 16S rRNA data  
17 15 correlate with fungal inhibition *in vitro* or *in vivo* as in Rebollar et al. 2019. This is particularly  
18 16 important given the recent push to develop probiotics using anti-Bd bacteria to manage  
19 17 chytridiomycosis (Bletz et al. 2013; Kueneman et al. 2016; McKenzie, Kueneman and Harris  
20 18 2018). Our study raises the need for future work to continue describing how differences in  
21 19 richness and frequency of beneficial bacteria influence host health as this may be an important  
22 20 precursor to the design of successful probiotic regimens (Bletz et al. 2013; Harrison et al. 2020).

23 21 Future studies can increase our understanding of the microbiomes of amphibians and  
24 22 other wildlife by incorporating techniques that characterize community functionality (e.g.  
25 23 metagenomics, transcriptomics), conducting range-scale and fine-scale microbiome surveys  
26 24 (Presley, Higgins and Willig 2010) studying how species characteristics (e.g. skin structure,  
27 25 immune responses, behavioral differences) shape skin microbiomes, or by evaluating the effects  
28 26 of environmental disturbances (e.g. fires) on host-associated microbiota.

## 28 28 SUPPLEMENTARY DATA

29 29 Supplementary data are available at FEMSEC online. This dataset has been deposited in  
30 30 the NCBI Sequenced Read Archive (SRA; accession number PRJNA731185). R code is  
31 31 available in the supplemental material.

## 32 32 FUNDING

33 33 This work was supported by the Northern California Herpetological Society Conservation  
34 34 Grant, the UC Berkeley Sponsored Projects for Undergraduate Research program, the National  
35 35 Science Foundation [1708926 to O.H.G] and [DEB 1557190 to E.B.R], and the Ford Foundation  
36 36 Fellows Program.

## 37 37 ACKNOWLEDGEMENTS

38 38 We would like to thank Delia Besanta, Max Lambert, and Telma Laurentino for their  
39 39 help with salamander sampling. Secondly, thank you to the Vincent J. Coates Genomics  
40 40 Sequencing Laboratory at the University of California - Berkeley for their help with sequencing.  
41 41 We appreciate the members of the OHG, Rosenblum, and Becker labs for their comments and  
42 42 suggestions on analysis and writing of the manuscript.

## Figure Legends

Figure 1: Sampling localities throughout the San Francisco Bay area. Locality colors are consistent with subsequent figures. The circle for Tilden Regional Park is split because there are two separate sampling locations within the park.

Figure 2: Core bacterial ASVs (Amplicon Sequence Variants) present in 70% or more of the samples from each genus of host salamander. Each color represents a different class of bacteria (blue (top) – Actinobacteria, violet – Alphaproteobacteria, pink – Betaproteobacteria, orange – Gammaproteobacteria, yellow (bottom) - Thermoleophilia), and each shade represents a distinct ASV. *Batrachoseps* exhibited a less conserved group of core microbiota across sampling localities.

Figure 3: Dot plots showing three alpha diversity metrics - (A) community richness, (B), Shannon Diversity Index, and (C) Faith's Phylogenetic Diversity. Mean values (long horizontal lines) and standard errors (short horizontal lines) are displayed. Significant groupings from pairwise comparisons are labeled using lowercase letters within each plot.

Figure 4: NMDS plots of terrestrial salamander bacterial communities built using (A) unweighted UniFrac (stress = 0.125645), and (B) Bray-Curtis (stress = 0.1735216) dissimilarities. Each point corresponds to the bacterial community on an individual, and distance between points correlates with dissimilarity among samples. In all three cases, variation with genus is observed.

Figure 5: NMDS plots of *Batrachoseps* (A & D), *Ensatina* (B & E) and *Taricha* (C & F) skin bacterial communities built using unweighted UniFrac (A, B & C) and Bray-Curtis dissimilarities (D, E and F). Points correspond to each community, and distance between points correlates with dissimilarity among samples.

Figure 6: Distribution of anti-Bd bacteria (columns) detected on the skin of individual salamanders (rows), where rows and columns are ordinated based on marginal probabilities. Sidebars display salamander genus, locality, site annual precipitation (PC1), temperature seasonality (PC2), body condition index, and percent natural cover (white – 50%, dark green – 100%). Significant associations between salamander ordination scores and sidebar variables are denoted with an asterisk at the top of the sidebar. (A) The microbiomes of salamanders from all genera exhibited a Clementsian metacommunity structure (positive and clumped inhibitory ASV replacements). (B) *Batrachoseps* exhibited Clementsian structure. (C) *Ensatina* exhibited Clementsian structure. (D) *Taricha* exhibited quasi-Clementsian structure.

Table 1: Linear mixed models selected using ranked AICc selection. The models evaluate the effects of temperature seasonality (Temp - PC1), annual precipitation (Prec - PC2), land use (% natural cover), and genus on alpha diversity metrics. To control for locality, we included it as a random variable.

Alpha Diversity Metric (Gaussian Distribution)	Variables Dropped	Variable(s) Kept	AICc of Final Model	ANOVA Results
Richness	% natural cover Temp - PC1 Prec - PC2	Genus	2411.6	Genus: $F_{2,182} = 8.72$ , $p = 0.001$
Shannon Diversity Index	% natural cover	Genus Prec - PC2 Temp - PC1	574.3	Genus: $F_{2,182} = 13.84$ , $p < 0.001$ Temp - PC1: $F_{1,5} = 4.19$ , $p = 0.385$ Prec - PC2: $F_{1,5} = 2.91$ , $p = 0.595$
Faith's Phylogenetic Diversity	% natural cover Temp - PC1	Genus Prec - PC2	1574.5	Genus: $F_{2,182} = 10.04$ , $p < 0.001$ Prec - PC2: $F_{1,6} = 2.45$ , $p = 0.674$

Table 2: PERMANOVA (adonis2) tests using a similar mix of fixed and random variables as described in the alpha diversity analyses. Distance matrices include unweighted UniFrac and Bray-Curtis dissimilarities. The model was stratified by locality.

Distance Metric	Variables	pseudo-F	R	p-value
<b>Unweighted UniFrac</b>	Genus	3.77	0.037	<b>0.004</b>
	Prec - PC2	3.79	0.019	1
	% natural cover	2.50	0.012	1
	Temp - PC1	2.01	0.010	1
<b>Bray-Curtis</b>	Genus	10.08	0.088	<b>0.004</b>
	Temp - PC1	9.67	0.042	<b>0.008</b>
	% natural cover	7.45	0.032	1
	Prec - PC2	6.15	0.026	1

Table 3: Metacommunity structure analysis results of the overall and anti-Bd ASVs recovered from the skin of San Francisco Bay Area salamanders. The elements of metacommunity structure (EMS) interpretations are presented in the rightmost column.

	<b>Coherence</b>	<b>Turnover</b>	<b>Clumping</b>	<b>Interpretation</b>
<b>Overall Skin Bacteria</b>	<b>Positive</b> Embedded absences: $6.04 \times 10^4$ Simulated mean: $6.57 \times 10^4 \pm 103.53$ , $p < 0.001$	<b>Positive</b> Replacements: $2.67 \times 10^7$ Simulated mean: $1.47 \times 10^7 \pm 1.22 \times 10^6$ , $p < 0.001$	<b>Positive</b> Morisita's index: 3.71, df = 189, $p < 0.001$	<b>Clementsian</b> - distribution of ASVs exhibits turnover with clumped boundaries across hosts
<b>Anti-Bd Bacteria</b>	<b>Positive</b> Embedded absences: $6.14 \times 10^3$ Simulated mean: $7.62 \times 10^3 \pm 132.82$ , $p < 0.001$	<b>Positive</b> Replacements: $6.41 \times 10^5$ Simulated mean: $3.77 \times 10^5 \pm 8.19 \times 10^4$ , $p = 0.001$	<b>Positive</b> Morisita's index: 4.07, df = 186, $p < 0.001$	<b>Clementsian</b> - distribution of ASVs exhibits turnover with clumped boundaries across hosts
