Received 3 December 2003/Accepted 18 February 2004

Pinus radiata (Monterey pine), a tree native to coastal California and Mexico, is widely planted worldwide for timber production. A major threat to Monterey pine plantations is the fungal disease pine pitch canker, caused by *Fusarium circinatum* (Hypocreales). We present a novel trapping approach using filter paper in combination with a rapid molecular method to detect the presence of inoculum in the air. The assay is also useful for diagnosing the presence of the pathogen on plants. The test is based on the *F. circinatum* specific primer pair CIRC1A-CIRC4A, which amplifies a 360-bp DNA fragment in the intergenic spacer region of the nuclear ribosomal operon. Real-time PCR was used to calculate the number of fungal spores present in each reaction mixture by comparing the threshold cycle (Ct) of unknown spore samples to the Ct values of standards with known amounts of *F. circinatum* spores. The filter paper method allows prolonged and more sensitive spore sampling in the field compared to traditional traps using petri dishes filled with selective medium. A field test at two sites in coastal California infested with pine pitch canker was carried out during the summer and fall of 2002. Spore counts were in the range of ca. 1×10^3 to ca. $7 \times 10^5/m^2$, with the highest spore counts in the fall, suggesting a seasonal fluctuation.

Monterey pine (*Pinus radiata* D. Don) is found in three native populations in the coastal range of California and in two insular populations in northwestern Mexico. This species is one of the most popular ornamental trees in the United States and is used widely for timber and pulp production in New Zealand, Australia, Chile, South Africa, and Spain (21).

The narrow genetic base of Monterey pine used in exotic and vast monoculture plantations is the cause of concern for the potential rise of destructive epidemics caused by either pests or pathogens (25). Pine pitch canker, caused by the ascomycete *Fusarium circinatum* Nirenberg and O'Donnell (= *F. subglutinans* [Wollenweb and Reinking] Nelson, Toussoun, and Marasas f. sp. *pini* [teleomorph: *Gibberella circinata* Nirenberg and O'Donnell]), is a serious disease of Monterey pine, with symptoms ranging from brown flagging of twigs, stem cankers associated with a strong ooze, dieback, and often tree death. Pine pitch canker was first detected in the southeastern United States (13) and was hypothesized to be endemic there and in Mexico (10, 12). More recently, the disease has been introduced into California (5, 10), South Africa (25), Japan (2), and Chile (26). Long-range spread of the disease may be connected to the movement of infected plant material for commercial use, including infected seeds.

Medium- and short-range dispersal of the pathogen is easily linked to the presence of abundant airborne inoculum (5, 8)

and may be enhanced by insects either by vectoring or by the creation of optimal infection courts through their feeding activity. Pathogen phoresy has been shown for insects in the families *Scolityidae*, *Anobiidae*, and *Cercopidae* (9, 11, 14, 20), but true vectoring still awaits experimental confirmation.

Both *G. circinata* mating types, *MAT-1* and *MAT-2*, are known to occur in nature, and their nucleotide sequences have been reported (7, 17, 23), but the importance of the sexual stage is poorly understood. Recent introductions of a pathogen into a new area are often characterized by the presence or at least dominance of a single mating type (e.g., in California, *MAT-1*) (24). As in other exotic pathosystems (*P. infestans*, etc.), subsequent introduction of the missing mating type is extremely likely.

Several molecular methods have been developed recently to differentiate *F. circinatum* from other species of the *G. fujikuroi* species complex. These include PCR-restriction fragment length polymorphisms (RFLPs) of the histone H3 gene (16) and mitochondrial RFLP (6). RFLP methods, however, are poorly suited for quantification of target DNA copy numbers, their sensitivity is likely to be too low for a reliable diagnosis directly from infected plant tissue, and this method can be problematic when plants have been infected by more than one *Fusarium* species. Molecular methods can be used to identify a *Fusarium* culture, but their utility can be better appreciated when identifying the pathogen directly from infected plants. Another important application of DNA-based diagnostics relies on its ability to be used directly on trapped spores, without the need for spores to be germinated. Inoculum pressure (e.g., spore load in the air) is of paramount importance in develop-

^a The specificity of the primer pair CIRC1A-CIRC4A was tested by using the strains belonging to *G. fujikuroi* clade 2.

^b Member of *G. fujikuroi* clade 2.

ing epidemiological models for most airborne diseases. All of the spore trapping methods used to date (e.g., bark washes, air sampling with petri dishes) include a step in which colony growth on a selective medium is observed and quantified. The

use of medium, which is prone to desiccation, effectively limits the trapping period to 1 to 3 days. The quantification step, involving colony counts, also presents some limitations, as plates can easily become overcrowded or overgrown, making precise counting impossible. Trapping methods suitable for long-term measurements in the field, matched with an alternative quantification approach, are highly desirable for epidemiological studies in which inoculum pressure needs to be determined.

The objectives of our study were (i) to establish a fast and reliable diagnostic test for the presence of *F. circinatum* independently of the presence of disease symptoms, (ii) to develop a new spore trapping assay that can be used for extended trapping periods and, (iii) to quantify airborne spores at infested sites with a real-time PCR assay.

MATERIALS AND METHODS

Fungal strains. The strains used in this study are listed in Table 1. The geographic origins and hosts or substrates of the 31 strains selected for sequencing of the nuclear ribosomal intergenic spacer (IGS) region have already been described (15), except for NRRL 26431 and NRRL 26432, which were isolated from *Pinus luchuensis* (Ryukyu Island pine) in Kyushu and Okinawa, Japan, respectively. All strains are stored in the Agricultural Research Service Culture Collection (Northern Regional Research Laboratory), National Center for Agricultural Utilization Research, Peoria, Ill.

Medium. *Fusarium* selective (FS) medium consists of the following per liter: 15 g of Bacto Peptone, 20 g of agar, 1 g of KH₂PO₄, 0.5 g of MgSO₄ · 7H₂O, 0.3 g of streptomycin sulfate, 0.1 g of ampicillin, 0.2 g of pentachloronitrobenzene (Aldrich, Milwaukee, Wis.), and 39 g of potato dextrose agar (Difco, Detroit, Mich.).

DNA isolation, amplification, and sequencing of fungal isolates. Strains were cultured and DNA was isolated as described by O'Donnell et al. (15). The concentrations of DNA from mycelium used for calculating the calibration curves were determined by UV spectrophotometry at 260 nm. Primers NL11 and CNS1 (Table 2) were used to amplify the entire IGS region with Platinum Taq DNA polymerase Hi-Fi (Invitrogen Life Technologies, Carlsbad, Calif.) in accordance with the supplier's recommendations, in a 9700 thermocycler (Applied Biosystems, Foster City, Calif.), with the following cycling parameters: 94°C for 90 s, 40 cycles of 94°C for 30 s, 52°C for 30 s, and 68°C for 3 min, followed by 68°C for 5 min and a 4°C soak. Amplicons were purified with Multiscreen plates (Millipore Corp., Bedford, Mass.) and then cycle sequenced with Applied Bio-

FIG. 1. Phylogenetic tree of 31 *Fusarium* strains based on parsimony analyses (heuristic search) of 2,593 bp of the nuclear ribosomal IGS region. The number above each internode represents the bootstrap interval from 1,000 replications. Strain numbers are those of the Agricultural Research Service Culture Collection (Northern Regional Research Laboratory). T = type strain.

systems BigDye chemistry version 2 in a 9700 cyler as follows: 96°C for 15 s, 40 cycles of 96°C for 15 s, 50°C for 10 s, and 60°C for 4 min, ending in a 4°C soak. The primers used for sequencing are listed in Table 2. Sequencing reaction mixtures were purified via ethanol precipitation and then run on a Prism 3100 genetic analyzer (Applied Biosystems-Hitachi, Tokyo, Japan). DNA sequences were edited and aligned with Sequencher 4.1.1.2 (Gene Codes, Ann Arbor, Mich.), and alignments were improved manually.

Phylogenetic analysis. The heuristic search option of PAUP* V4.0b4a (22) was used with 1,000 random addition sequences to conduct a maximum-parsimony analysis of the aligned IGS sequences, after excluding 37 ambiguously aligned nucleotide positions. Of the 2,593 included characters, 382 and 485 were autapomorphic and synapomorphic, respectively. On the basis of the results of a previous phylogenetic analysis (15), a sequence of *F. oxysporum* NRRL 22902 was used to root the parsimony tree by the outgroup method. Clade stability was assessed via 1,000 parsimony bootstrap replications with PAUP* (22).

DNA extraction from spores. Spore suspensions (100 μ l) were mechanically disrupted by shaking with glass beads (0.5 mm; Biospec Products, Inc., Bartlesville, Okla.) for 30 s. After addition of 0.3 ml of cetyltrimethylammonium bromide extraction buffer (15), the samples were subjected to three freeze-thaw cycles (2 min on dry ice, 2 min at 75°C, repeated three times with the last thaw extended to 30 min). DNA was extracted with 0.35 ml of phenol-chloroform-isoamyl alcohol, followed by purification with the GeneClean kit (Bio 101, Inc., Carlsbad, Calif.), in accordance with the instructions supplied by the manufacturer. DNA from fungal colonies grown on FS medium was extracted by a "hyphal tipping" method in which mycelium was suspended in 100 μ l of distilled water, frozen on dry ice for 3 min, thawed at 75°C, and vortexed for 2 min. Freezing and thawing were repeated three times, with the last thaw extended to 15 min. Samples were centrifuged for 5 min at 15,700 \times g, and 6.25 μ l of the supernatant was used for PCRs.

Primers for specific detection of *F. circinatum*. Specific primers for *F. circinatum* (CIRC1A and CIRC4A; Table 2) were designed with primer3 software (www-genome.wi.mit.edu/cgi-bin/primer/primer3_www.cgi) on the basis of the alignment of the nuclear ribosomal IGS region of the 31 *Fusarium* strains and synthesized by Qiagen-Operon (Alameda, Calif.). The amplicon size is 360 bp. The specificity of the primers used to amplify *F. circinatum* DNA was tested with a PCR comparison of *F. circinatum* strains with all strains belonging to the same

clade (clade 2) of the *G. fujikuroi* complex on the basis of the IGS tree (Fig. 1). The PCR mixture contained 12 μ l of H₂O, 2.5 μ l of PCR buffer, 1.0 μ l of 50 mM MgCl₂, 2.5 μ l of deoxynucleoside triphosphate, 0.25 μ l of 50 mM primer CIRC1A, 0.25 μ l of 50 mM primer CIRC4A, 0.25 μ l of Platinum *Taq* polymerase, and 6.25 μ l of template DNA. The annealing temperature for the primers was tested in the range of 58.0 to 70.0°C. The optimal cycling profile was denaturation at 94.0°C for 180 s, followed by 45 cycles of 94°C for 35 s, 66°C for 55 s, and 72°C for 50 s and a final extension of 72°C for 12 min.

Determination of the mating type. The mating type was determined in a multiplex PCR with the primers listed in Table 2 as described by Covert et al. (7) and Wallace and Covert (23). DNA standards of strain NRRL 25331 (*MAT-1*) in the range of 10¹ to 10⁴ pg were used to measure the detection limit for this single-copy gene.

Environmental samples may consist of a mixture of strains of both mating types in different concentrations. In order to simulate this condition, DNA templates consisting of mixtures of strains NRRL 25331 (*MAT-1*) and NRRL 25333 (*MAT-2*) at relative concentrations of 1:1, 1:10, 1:100, and 1:1,000 were used in a multiplex reaction.

Real-time PCR. Real-time PCRs with both CIRC1A-CIRC4A and the mating type primers sets were carried out with the iCycler from Bio-Rad (Hercules, Calif.). The SYBR-Green method used SYBR-Green I (Applied Biosystems) as a fluorescent dye, which intercalates specifically with double-stranded DNA during the extension phase of the PCR. For quantification of the starting amount of template DNA, the threshold cycle (Ct) for each sample was calculated. The Ct value, which is the cycle number when the fluorescence of SYBR-Green measured is significantly different from the background level for the first time, was calculated for baseline cycles 2 to 10. The Ct value is proportional to the logarithm of the initial DNA concentration. The data analysis window was set at 10.00% of a cycle and centered at the end of the cycle. The real-time PCR conditions were as follows: 8.0 μ l of H₂O, 2.5 μ l of PCR buffer, 2.5 μ l of 50 mM MgCl₂, 2.5 μ l of deoxynucleoside triphosphate, 0.25 μ l of 50 mM forward primer, 0.25 μ l of 50 mM reverse primer, 1.25 μ l of SYBR-Green, 1.25 μ l of fluorescein (Bio-Rad), 0.25 μ l of Platinum *Taq* polymerase, and 6.25 μ l of template DNA. Cycling parameters were as follows: 94.0°C for 180 s, 45 cycles of 94°C for 35 s, 66°C for 55 s, and 72°C for 50 s, followed by a final extension of 72°C for 12 min. Standard curves were calculated for DNAs from *F. circinatum* NRRL 25331

FIG. 2. Specificity of the primer pair CIRC1A-CIRC4A for the amplification of a 360-bp fragment in the nuclear ribosomal IGS region of *F. circinatum*. An ethidium bromide-stained agarose gel of PCR products amplified from strains belonging to the American clade of the *G. fujikuroi* complex and two environmental samples from spore traps is shown. Lanes: 1, 100-bp DNA ladder (Promega); 2, water negative control; 3, *F. circinatum* NRRL 25331; 4, *F. circinatum* NRRL 25332; 5, *F. circinatum* NRRL 25333; 6, *F. circinatum* NRRL 25621; 7, *F. circinatum* NRRL 26431; 8, *F. circinatum* NRRL 26432; 9, *F. circinatum* NRRL 25707; 10, environmental sample from San Francisco, Calif. (site I); 11, environmental sample from San Bruno, Calif. (site II); 12, *F. subglutinans* NRRL 22016; 13, *Fusarium* sp. strain NRRL 25204; 14, *Fusarium* sp. strain NRRL 25622; 15, *Fusarium* sp. strain NRRL 26756; 16, *Fusarium* sp. strain NRRL 26757; 17, *Fusarium* sp. strain NRRL 25346; 18, *Fusarium* sp. strain NRRL 25623; 19, *Fusarium* sp. strain NRRL 25195; 20, *Fusarium* sp. strain NRRL 25807; 21, *Fusarium* sp. strain NRRL 29123; 22, *F. bulbicola* NRRL 13618; 23, *F. bactrioides* NRRL 20476; 24, *F. succisae* NRRL 13613; 25, *F. anthophilum* NRRL 13602; 26, *F. begoniae* NRRL 25300; 27, water negative control; 28, DNA ladder.

(type strain, *MAT-1*) and NRRL 25333 (*MAT-2*) obtained from mycelium at a concentration of 10^1 to 10^4 pg per reaction. For direct comparisons with environmental samples, additional standard curves were calculated with spore suspensions at concentrations of 10^5 , 10^4 , 10^3 , and 10^2 spores per 100 μ l. Three independent amplifications were conducted for each DNA concentration and strain. Melting curves were measured for 110 cycles of 10 s each, starting at 60°C and increasing by 0.3°C each cycle. The melting curve is displayed as the negative first derivative of the fluorescence-versus-temperature plot $[-d(RFU)/dT]$ over temperature. The iCycler software identifies the so-called “melting peaks” and assigns melting temperatures from this plot (1). PCR products were subjected to gel electrophoresis by loading 5 μ l of each PCR product onto a 1.5% agarose gel, running it for 60 min at 20 V/cm, and staining it with ethidium bromide prior to visualization over UV.

Environmental test. Spore traps were placed on two sites. Site I was Presidio National Park, San Francisco, Calif., and site II was San Bruno, Calif. Both sites are nonnative stands of *P. radiata*. Trees at site I showed light symptoms of pine pitch canker (<25% of the trees), while trees at site II were heavily infected, with numerous dead or dying trees (ca. 90% of the trees were infected). Three platforms (height, 1 m) were placed on each site at a distance of ca. 25 m from each other, each holding a petri dish with FS medium and a filter paper (Whatman no. 1). To increase its trapping capacity, each filter paper was wetted with 4 \times TE buffer (40 mM Tris HCl, 4 mM EDTA; Sigma Chemical Co., St. Louis, Mo.). Samples were collected from the field after 2 weeks in June, July, and October of 2002 and processed in the laboratory by three different methods.

Method 1 (growth on FS medium). Petri dishes containing FS medium were cultured for 2 weeks at room temperature, at which time fungal colonies were examined morphologically and counted. The number of *F. circinatum* colonies growing on each petri dish (surface area, 56.34 cm²) was transformed to the number per square meter.

Method 2 (growth on filter paper). Twenty percent of the surface of the filter paper was cut into pieces of ca. 5 mm² each and laid over FS medium. After 2 weeks of incubation at room temperature, the number of *F. circinatum* colonies was transformed to the number per square meter (area of Whatman no. 1 filter paper, 0.0095 m²; 20%, i.e., 0.0019 m², was used for culture growth). To test the cospecificity of the cultures with *F. circinatum*, two representative cultures per plate (methods 1 and 2) were analyzed by PCR with the primer pair CIRC1A-CIRC4A.

Method 3 (real-time PCR). Spores from the remaining filter paper (80% of the surface) were washed with 20 ml of hot (65°C) 4 \times TE buffer and resuspended by vortexing (maximum speed) for 5 min. The suspensions were centrifuged at 1,000 \times g for 90 min to concentrate the spores. After the supernatant was removed, DNA was extracted from the pellet (100 μ l). To prove the efficacy of the spore harvest, 0.3 ml of the supernatant and the filter paper were plated on FS medium, incubated at room temperature for 2 weeks, and inspected for fungal growth. DNA extracts of the spores were amplified by real-time PCR. The resulting Ct values were used for quantification of the starting copy number of *F. circinatum* DNA in each reaction mixture by interpolation of the standard curve of known DNA and spore concentrations. The value obtained was multiplied by 131.6 to calculate the concentration of *F. circinatum* per square meter (the surface size of the filter was 0.0076 m²).

Statistical analyses. Analysis of variance was performed with JMP 5.0.1 software (SAS Institute Inc., Cary, N.C.). Multiple comparisons were performed

with the Tukey-Kramer honestly significant difference test. Pairwise comparisons were done with Student's *t* test.

Nucleotide sequence accession numbers. The nucleotide sequences determined in this study have been deposited in the GenBank database under accession numbers AY249379 to AY249409.

RESULTS

DNA sequencing. The nuclear ribosomal IGS region from 30 *Fusarium* strains in the *G. fujikuroi* species complex and the outgroup *F. oxysporum* were sequenced (the accession numbers are in Table 1). The lengths of the fragments ranged from ca. 2,600 to 2,650 bp. Maximum-parsimony analysis of the aligned IGS sequences yielded a single most-parsimonious tree with a length of 1,695 steps (consistency index = 0.65, retention index = 0.73) in which three clades of the *G. fujikuroi* complex were strongly supported by bootstrapping (Fig. 1).

F. circinatum was deeply nested within clade 2. Two strongly supported subclades were resolved among the exclusive group of *F. circinatum* strains (100% bootstrap): (i) NRRL 25331 ex *P. radiata* (Monterey pine) from Georgia and NRRL 25621 ex *P. patula* (Mexican yellow pine) from South Africa (98% bootstrap) and (ii) NRRL 26431 and NRRL 26432 ex *P. luchuensis* from Kyushu and Okinawa, Japan, NRRL 25332 ex *P. taeda* (Loblolly pine) from Georgia, NRRL 25707 ex *P. caribaea* (Caribbean pine) from North Carolina, and NRRL 25333 ex *P. patula* from South Africa (87% bootstrap).

Primer design. A primer pair specific for *F. circinatum* (CIRC1A-CIRC4A) was designed with the primer3 software on the basis of an alignment of the IGS regions of the 31 *Fusarium* strains (Table 2). The 360-bp amplicon predicted from the sequence data size was confirmed by gel electrophoresis (Fig. 2).

Specificity of the primers. The specificity of the primers was shown by PCR analyses of *F. circinatum* strains belonging to both subclades and other fusaria belonging to clade 2 of the *G. fujikuroi* complex (Fig. 2). With an annealing temperature of 66°C or higher, only DNA from *F. circinatum* (both subclades) was amplified.

Determination of linear range of quantification for real-time PCR. Standard curves were calculated for both the multicopy IGS and the single-copy mating type loci *MAT-1* and *MAT-2* (Fig. 3). Curves were determined independently in

FIG. 3. Standard curves quantifying DNAs of *F. circinatum* strains NRRL 25331 (*MAT-1*) and NRRL 25333 (*MAT-2*) obtained by real-time PCR with SYBR-Green as the fluorescent dye. Ct values, corresponding to the increase in template DNA above the background level, were plotted against the log of genomic DNA standards of known concentrations ($n = 3$). DNA amplification was done with the primer combination CIRC1A-CIRC4A for the multicopy ribosomal *IGS* gene and the primer pairs for the single-copy mating type genes *MAT-1* and *MAT-2*, respectively. (A) Standard curves obtained with DNA extracted from mycelium in the range of 10^1 to 10^4 pg per reaction. (B) Standard curves obtained with DNA extracted from a spore suspension in the range of 10^2 to 10^5 spores/100 μ l.

triplicate for DNA extracted from mycelium and from spores of isolates bearing different mating types. In order to obtain comparable data sets for quantification of DNA extracted from spores, an initial spore suspension of 100 μ l was used for calibration and for environmental samples. The correlation between Ct and known DNA content in a 10-fold dilution series was high for both mycelium (strain NRRL 25331 $R^2 = 0.9987$, strain NRRL 25333 $R^2 = 0.9993$) and spores (strain NRRL 25331 $R^2 = 0.9920$, strain NRRL 25333 $R^2 = 0.9997$) with amplification of the multicopy locus *IGS*. With this primer set, the correlation between Ct and DNA concentration was linear from 10^1 to 10^4 pg and from 10^2 to 10^5 spores/100 μ l, and the lower reliable detection threshold was 10 pg or 10^2 spores/100 μ l. With the single-copy mating type genes, 10 pg of DNA was still detectable on an agarose gel (data not shown), but detection by real-time PCR was unreliable because of low

melting peaks that were hardly distinguishable from the background. With this method, detection became reliable at a DNA concentration of 10^2 copies per reaction. Furthermore, the Ct values of the mating type genes at the lowest DNA concentration (10^1 pg) did not always fit in a linear inverse regression. Ct values of the single-copy genes were higher than those obtained for corresponding concentrations with the multicopy set. The Ct difference (Δ Ct) between the two sets averaged 6.1 ± 1.2 (standard deviations [SD]) in the range linear for both methods (10^2 to 10^4 pg and 10^3 to 10^5 spores/100 μ l).

Melting curve analyses. Specificity of PCR amplicons was measured by calculating the melting curves of double-stranded DNA (Fig. 4). The negative first derivative of the fluorescence-versus-temperature ($-dF/dT$) plot over temperature displays a melting peak, which is a function of fragment length and base composition, i.e., the relative concentration of pyrimidines.

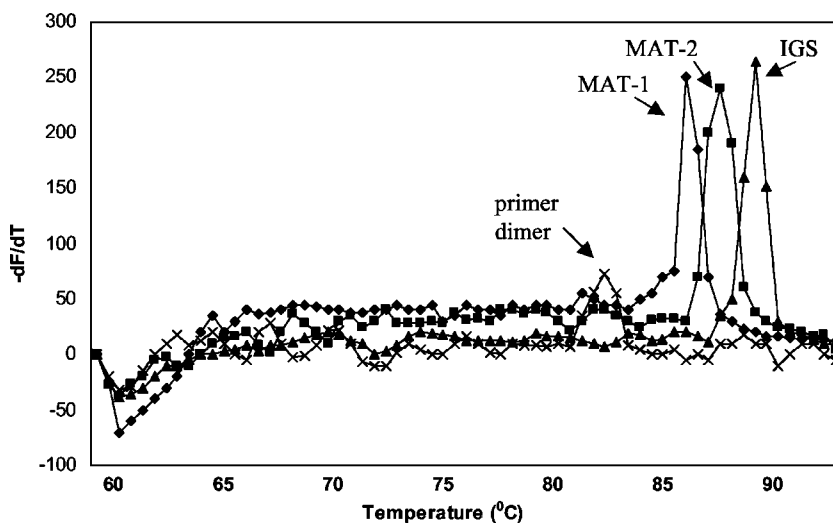

FIG. 4. Melting curves of *F. circinatum* DNA amplicons as measured by real-time PCR. Displayed is the negative first derivative of the fluorescence-versus-temperature plot over temperature ($-dF/dT$ versus temperature). Fragments of the IGS region and the two mating type genes (*MAT-1* and *MAT-2*) can be distinguished by their respective melting temperatures, which are a function of percent G+C content and fragment length. Primer dimers (if present) show a melting peak at ca. 82°C.

The IGS fragment amplified with the primer pair CIRC1A-CIRC4A gives a melting peak at ca. $88.0 \pm 0.5^\circ\text{C}$. The fragments of the mating type genes *MAT-1* and *MAT-2* have melting peaks at 85.5 ± 0.5 and $87.0 \pm 0.5^\circ\text{C}$, respectively. Primer dimers (if present) show a melting peak at ca. $82.0 \pm 2.0^\circ\text{C}$.

Environmental spore sampling. *F. circinatum* spores from both sites were detected and quantified by three different methods. For a summary of the numbers of spores from three independent experiments per site and method, see Fig. 6.

Method 1: FS medium. FS medium remained stable at both field sites for only 1 to 3 days. When plates were collected after 1 or 2 weeks, the medium had dried out and fungal colonies were barely visible. The average numbers of *F. circinatum* spores from three spore traps collected in June 2002 after 2 weeks in the field were $(2.40 \pm 0.4) \times 10^3/\text{m}^2$ at site I and $(3.20 \pm 0.6) \times 10^3$ at site II. The corresponding values for spore traps collected in July 2002 were $(2.70 \pm 0.5) \times 10^3/\text{m}^2$ at site I and $(4.00 \pm 0.4) \times 10^3/\text{m}^2$ at site II. In October 2002, slightly more were counted, i.e., $(0.99 \pm 0.07) \times 10^4/\text{m}^2$ at site I and $(5.03 \pm 0.4) \times 10^4/\text{m}^2$ at site II. To ensure that the counted white colonies really were *F. circinatum*, DNA was extracted from two representative samples per plate by the hyphal tipping method and the IGS region was amplified with the selective primers CIRC1A and CIRC4A.

Method 2: traps using filter paper. Filter paper (Whatman no. 1) was stable for 2 weeks in the field without showing any physical degradation. No visible fungal growth was observed on the paper when collected from the field, but after plating of small paper particles (20% of the paper surface) on FS medium, abundant fungal growth was observed after incubation at room temperature for 1 to 2 weeks. Primers CIRC1A and CIRC4A were used as described above to ensure that growing colonies were *F. circinatum*. The average numbers of *F. circinatum* spores collected with three spore traps in June 2002 were $(11.45 \pm 0.2) \times 10^3/\text{m}^2$ at site I and $(10.42 \pm 1.1) \times 10^3/\text{m}^2$ at site II. The corresponding numbers for July 2002

were $(29.00 \pm 2.4) \times 10^3/\text{m}^2$ at site I and $(21.90 \pm 5.4) \times 10^3/\text{m}^2$ at site II. The numbers of spores counted in October 2002 were $(1.15 \pm 0.03) \times 10^5/\text{m}^2$ at site I and $(1.43 \pm 0.20) \times 10^5/\text{m}^2$ at site II.

Method 3: real-time PCR quantification of spores on filter paper. The remaining 80% of the filter paper surface was used for molecular quantification. *F. circinatum* DNA was extracted from filter paper collected at both sites I (Presidio) and II (San Bruno) and used as the template for real-time PCR amplification (Fig. 5).

For samples collected in June 2002, the average Ct value from three spore traps was 31.4 ± 2.5 at site I. At site II, one spore sample failed to give an amplification product; the aver-

FIG. 5. Ct values of DNA extracted from airborne conidia of *F. circinatum* were estimated by real-time PCR of a fragment of the IGS region. Environmental samples were collected from spore traps in San Francisco (site I; June 2002, boldface open circle; July 2002, filled circle; October 2002, lightface open circle) and San Bruno (site II; June 2002, dotted diamond; July 2002, filled diamond; October 2002, bisected diamond), Calif. Standardization was done with DNA extracted from spores of *F. circinatum* NRRL 25331.

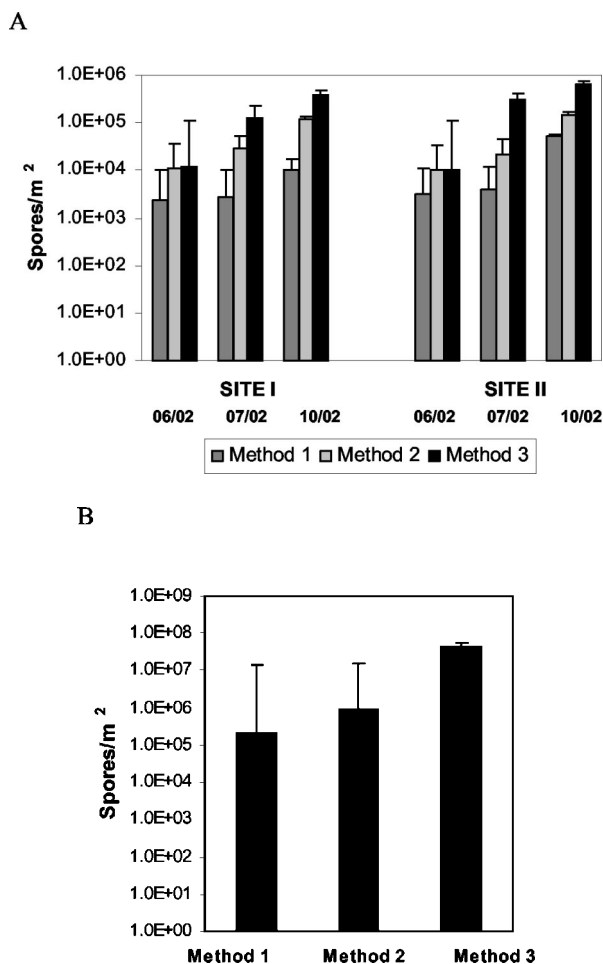

FIG. 6. Quantification of *F. circinatum* from spore traps collected after 2 weeks in the field at San Francisco (site I) and San Bruno (site II), Calif. Three spore collection methods were used: 1, trapping with FS medium; 2, trapping with filter paper and subsequent transfer of the paper to FS medium; 3, trapping on filter paper and subsequent real-time PCR with the primer pair CIRC1A-CIRC4A. (A) Numbers of spores were calculated individually for each site, sampling point, and sampling method. (B) Cumulative numbers of spores for each sampling method combining the numbers from all sites and sampling points (vertical bars represent standard errors). Spore counts obtained by method 3 are significantly different from spore counts obtained by methods 1 and 2 (multiple-comparison analysis of variance with the Tukey-Kramer honestly significant difference test, $P = 0.05$).

age Ct of the two remaining spore samples was 32.5 ± 2.5 . The corresponding numbers of spores, calculated by plotting against the calibration curve of spores (Fig. 3B), were $12.0 \times 10^3/\text{m}^2$ for site I and $9.9 \times 10^3/\text{m}^2$ for site II. For samples collected in July 2002, the average Ct values from three spore traps were 27.7 ± 0.9 at site I and 26.9 ± 1.3 at site II; the corresponding numbers of spores were $1.25 \times 10^5/\text{m}^2$ and $3.00 \times 10^5/\text{m}^2$, respectively. For samples collected in October 2002, the average Ct values from three spore traps were 26.6 ± 0.1 at site I and 25.8 ± 0.2 at site II; the corresponding numbers of spores were $3.95 \times 10^5/\text{m}^2$ and $6.38 \times 10^5/\text{m}^2$, respectively. The spore counts obtained by the three methods are summarized in Fig. 6B. Cumulatively for all sampling times and sites combined, method 1 yielded 2.18×10^5 spores/ m^2 ($n = 18$, SD

$= 0.18 \times 10^5$), method 2 yielded 9.92×10^5 spores/ m^2 ($n = 18$, SD = 0.55×10^5), and method 3 yielded 44.30×10^5 spores/ m^2 ($n = 18$, SD = 2.31×10^5). No significant difference was detected between methods 1 and 2, but spore counts obtained by sampling method 3 were significantly higher (multiple-comparison analysis of variance with the Tukey-Kramer honestly significant difference test, $P = 10^{-4}$).

No significant difference (Student's t test, $P = 0.1173$) was observed when comparing the numbers of spores obtained at sites I and II by method 3. Site I had a cumulative number of 15.96×10^5 spores/ m^2 for all three sampling times ($n = 9$, SD = 1.70×10^5), and site II had a cumulative number of 28.33×10^5 spores/ m^2 ($n = 9$, SD = 2.64×10^5). The lack of difference in spore counts between the two sites was also observed when treating each sampling time independently.

To study the effect of seasonality, the cumulative numbers of spores for both sites obtained by method 3 were compared. In June 2002, 0.56×10^5 spores/ m^2 ($n = 6$, SD = 0.01×10^5) were counted, in July, 12.75×10^5 spores/ m^2 ($n = 6$, SD = 0.96×10^5) were counted, and in October, 30.99×10^5 spores/ m^2 ($n = 6$, SD = 1.33×10^5) were counted. Differences among the three sampling times were significant (Tukey-Kramer honestly significant difference test, $P = 10^{-4}$).

Mating type analyses. The PCR-based mating type assay for *F. circinatum* developed by Wallace and Covert (23) was used to amplify the idiomorphs of the mating type genes in a multiplex PCR with four primers. Amplicons were distinguished by their sizes: approximately 380 bp for *MAT-1* versus approximately 190 bp for *MAT-2*. Four *F. circinatum* strains from different geographic origins were used as a positive control. *F. circinatum* strains NRRL 25331 (Georgia) and NRRL 26431 (Japan) gave a positive signal for *MAT-1*, whereas *F. circinatum* strains NRRL 25332 (Georgia) and NRRL 25333 (South Africa) possess the *MAT-2* idiomorph. We tested the mating type of the environmental *F. circinatum* samples with pooled DNA from the filter paper traps, which had been identified with the primer pair CIRC1A-CIRC4A. DNA from representative colonies growing on FS medium (at least two per plate) was extracted by the hyphal tipping method and tested for mating type. All environmental samples from our two study sites analyzed so far belong to the *MAT-1* mating type (data not shown).

Multiplex PCR with DNA mixtures of both mating types resulted in two distinct fragments on the agarose gel even when the initial relative concentrations differed in a range of 2 orders of magnitude (data not shown). DNA from *F. circinatum* strain 25331 (*MAT-1*) was mixed with DNA from strain 25333 (*MAT-2*) at relative concentrations of 1:1, 1:100, and 1:1,000. The PCR resulted in the amplification of two fragments of the expected size for the mating type genes (*MAT-1*, 380 bp; *MAT-2*, 190 bp) with initial relative template concentrations of 1:1, 1:10, and 1:100. When one of the two mating type genes was present at a relative concentration of 0.1% (1:1,000), no fragment of the corresponding size was amplified.

DISCUSSION

In this paper we describe a new method for the detection and quantification of *F. circinatum*, the causal agent of pine pitch canker. The test is based on the use of the species-specific

primer pair CIRC1A-CIRC4A, which amplifies a 360-bp fragment of the nuclear ribosomal IGS region. *F. circinatum* clusters within the so-called "American clade" sensu O'Donnell (15) of the *G. fujikuroi* complex (called clade 2 in our analyses) and is the only known pathogen of conifers in this complex. The primer pair CIRC1A-CIRC4A appears to be specific for *F. circinatum* (both subclades) since it does not amplify the IGS from closely related species in clade 2. New species belonging to the *G. fujikuroi* complex were discovered recently (2, 27), and cryptic speciation within the complex might occur (18), making it very probable that the full diversity of the complex has not yet been detected. With the exception of new species bearing an IGS sequence identical to that of *F. circinatum*, sequencing of the CIRC1A-CIRC4A amplicon can be used to confirm the identity of the tested samples. In the course of this study, amplicons were routinely sequenced to ensure that only the target species was being amplified.

One of the main objectives of this study was to establish a method for quantifying *F. circinatum* spores from air samples. Calibration curves based on DNA extracted from known amounts of spores were the most appropriate standard. A 10-fold dilution series ranging from 10^2 to 10^5 spores/100 μ l was in linear inverse regression when plotted against Ct values of both the multicopy and single-copy primer sets. A comparison of multicopy versus single-copy regressions indicated that (i) quantification was more reliable at lower DNA concentrations for primers based on the multicopy IGS locus (10^2 spores/100 μ l) than for primers based on the single-copy mating alleles (10^3 spores/100 μ l) and (ii) at any spore concentration, the Ct value obtained with the multicopy primer set will be lower than that obtained with the single-copy set (average Δ Ct = 6.1 ± 1.2) (Fig. 3). The exact copy number of the rRNA gene region of *F. circinatum* or any other *Fusarium* species has not been measured yet to our knowledge. Our analysis of the comparative sensitivities of the two assays is in agreement with a ca. 100-fold higher copy number of the ribosomal operon compared to the mating type genes.

The assay has been successfully used to detect the presence of the pathogen directly from infected plant tissue, sometimes also from asymptomatic plants (data not shown). Several species within the *G. fujikuroi* complex are known to be endophytic in their respective hosts. It has been hypothesized that *F. circinatum* may also remain dormant within the host without causing symptoms of disease for an extended period of time (19). Furthermore, the pathogen was also isolated from pine cones of symptomless trees in Mexico (3).

Measurements of airborne inoculum over an extended period of time are essential for epidemiological studies. We compared airborne inocula at three different times at two sites in California with differential incidences of pine pitch canker. In three parallel experiments, we compared the number of spores obtained from a traditional spore trap with FS medium (method 1) with the number of spores trapped on filter paper subsequently plated on FS medium (method 2) and with the number of spores obtained with filter paper and subsequent DNA extraction and real-time PCR (method 3). The field results indicate comparable concentrations of airborne *F. circinatum* spores in both *P. radiata* stands. In all experiments, the numbers of spores obtained with filter paper (methods 2 and 3) were higher than the number of spores obtained with FS me-

dium (method 1), although the difference was significant only for method 3 ($P = 10^{-4}$). This fact can be explained by the rapid degradation and drying of the medium after 2 to 3 days in the field. Method 1 is therefore not suited for long-term spore sampling. On the other hand, filter paper showed no sign of physical degradation after 2 weeks in the field. The higher counts obtained by real-time PCR (method 3) compared to culturing (method 2) can be explained in part by the slow and retarded growth of some fungal colonies on filter paper because faster-growing colonies had occupied most of the available resources. In addition, several non-*Fusarium* fungi were able to colonize the medium, competing with *F. circinatum* colonies for resources. In this study, we could not determine the spore type of the trapped *F. circinatum* spores. Therefore, the relative frequency of multicelled macroconidia in relation to one-celled microconidia or the number of spores germinating on the filter paper was not quantified and might also be responsible for some of the observed differences.

A clear effect of season on spore production was observed in this study. Samples obtained in June 2002 at both sites reached a total of 0.56×10^5 spores/m² ($n = 6$, SD = 0.01×10^5). One out of three samples from site II did not contain an *F. circinatum*-specific DNA fragment. The numbers of spores from samples collected in July and October of 2002 reached total levels of 12.75×10^5 /m² ($n = 6$, SD = 0.96×10^5) and 30.99×10^5 /m² ($n = 6$, SD = 1.33×10^5), respectively. Airborne inoculum of *F. circinatum* at various levels throughout the year at an infested site near Santa Cruz, Calif., was also observed by Correll et al. (5). Temperature, moisture, and availability of nutrients most probably play a crucial role in spore production.

The relatively high number of spores from site I, which shows a low level of disease, might be explained by the fact that the traps at site I were relatively protected by the shade of neighboring trees. Traps at site II were much more exposed to the sun and UV radiation. Consequently, plates from site II were always drier than those from site I. In addition, site I was subjected to more fog on a regular basis than site II. It is also probable that the dead trees at site II, although providing a striking visual diagnostic trait of an infested site, may not contribute to inoculum production. *F. circinatum* isolation success is in fact higher when slightly symptomatic living plant tissue is used rather than dead plant material.

F. circinatum has been shown to be heterothallic on the basis of vegetative compatibility tests and mating type segregation (4). In order to assess the mating type of the field isolates of *F. circinatum*, a multiplex PCR was performed with primer sets previously developed (7, 23). The primer sets are not specific for *F. circinatum* but amplify the mating type loci of a number of closely related *Fusarium* species. When both mating types are detected at a site, it is critical to ensure that the results are not due to cross-reactivity with other *Fusarium* species. In this study, we have determined Δ Ct values with primers for the multicopy IGS region and the single-copy mating type genes. This difference remains constant for DNA concentrations ranging from 10^2 to 10^4 pg and from 10^2 to 10^5 spores/100 μ l. At DNA concentrations lower than 10^2 pg and 10^3 spores/100 μ l, the signal from the single-copy primers becomes unreliable and the linearity of the corresponding standard curve is lost. A Δ Ct value smaller than that reported in this study indicates that the mating type primers are also amplifying a number of non-

circinatum spores, and the results should be verified by an alternative method if both mating types are detected.

Multiplex PCRs with both primer sets on mixtures of DNAs from isolates with different mating types indicated that it is possible to detect both types even at very uneven ratios (1:100). In our study, only *MAT-1* was amplified at both sites; thus, no further validation of the data was necessary. The prevalence of *MAT-1* is in agreement with results from previous studies and is consistent with the hypothesis that *F. circinatum* arrived relatively recently in California (10, 24).

The results presented here demonstrate that an improved trapping method for aerial spores of *F. circinatum* with filter paper combined with species-specific real-time PCR amplification can improve spore detection significantly compared to more traditional approaches. The real-time PCR method offers the following advantages: (i) it is a diagnostic technique with increased sensitivity and higher selectivity that is independent of the presence of symptoms, (ii) it has the ability to quantify airborne conidia continuously at low cost for long periods of time, and (iii) DNA extracts used for identification and quantification can also be used for mating type or other genetic analyses of bulk collections of spores, thus enhancing our ability to detect the arrival of new genotypes, strains, or mating types.

ACKNOWLEDGMENTS

We thank the Presidio Trust and the State of California for the use of the field sites. For technical assistance we thank D. Schmidt and M. A. Smith.
